Abstract

Gaining a genomic perspective on phylogeny requires the collection of data from many putatively independent loci across the genome. Among insects, an increasingly common approach to collecting this class of data involves transcriptome sequencing, because few insects have high-quality genome sequences available; assembling new genomes remains a limiting factor; the transcribed portion of the genome is a reasonable, reduced subset of the genome to target; and the data collected from transcribed portions of the genome are similar in composition to the types of data with which biologists have traditionally worked (e.g. exons). However, molecular techniques requiring RNA as a template, including transcriptome sequencing, are limited to using very high-quality source materials, which are often unavailable from a large proportion of biologically important insect samples. Recent research suggests that DNA-based target enrichment of conserved genomic elements offers another path to collecting phylogenomic data across insect taxa, provided that conserved elements are present in and can be collected from insect genomes. Here, we identify a large set (n = 1510) of ultraconserved elements (UCEs) shared among the insect order Hymenoptera. We used in silico analyses to show that these loci accurately reconstruct relationships among genome-enabled hymenoptera, and we designed a set of RNA baits (n = 2749) for enriching these loci that researchers can use with DNA templates extracted from a variety of sources. We used our UCE bait set to enrich an average of 721 UCE loci from 30 hymenopteran taxa, and we used these UCE loci to reconstruct phylogenetic relationships spanning very old (≥220 Ma) to very young (≤1 Ma) divergences among hymenopteran lineages. In contrast to a recent study addressing hymenopteran phylogeny using transcriptome data, we found ants to be sister to all remaining aculeate lineages with complete support, although this result could be explained by factors such as taxon sampling. We discuss this approach and our results in the context of elucidating the evolutionary history of one of the most diverse and speciose animal orders.

Keywords: arthropods, baits, conserved sequence, Hymenoptera, probes, target enrichment, ultraconserved elements

Introduction

The insect order Hymenoptera (ants, bees, wasps and sawflies) is one of the most diverse animal orders (Grimaldi & Engel 2005), including at least 125 000 species (Gaston 1991; LaSalle & Gauld 1993; Gaston et al. 1996; Sharkey 2007) and comprising approximately 8% of all described animals (Davis et al. 2010). In addition to being hyperdiverse, hymenopterans are also incredibly abundant: ants alone occur in almost all terrestrial habitats and may constitute 15–20% of animal biomass in tropical rainforests. Other aculeate groups such as vespid wasps (hornets and yellow jackets) and stingless honey bees may account for an additional 15–20% (Fittkau & Klinge 1973). The ecological roles held by hymenopterans are diverse and include predator, prey, scavenger, parasite, ectosymbiont and mutualist. Species within the order also play critical roles in worldwide pollination of agricultural crops and natural vegetation (Roubik 1995; Kevan 1999; Michener 2007), tropical forest dynamics (Roubik 1989; Levey & Byrne 1994).
ecosystem services (Kremen et al. 2002; Del Toro et al. 2012) and biological control of pest insects (Quicke 1997). Outside of their biological importance, hymenopteran taxa are models for understanding the evolution and genetic basis of social behaviour (Bourke & Franks 1995; Smith et al. 2008; Bradley et al. 2009; Johnson & Linksaver 2010; Howard & Thorne 2010; Wang et al. 2013), mechanisms of sex determination (Hunt & Page 1994; Beye et al. 1994; Page et al. 2002), evolution of adaptive specialization (Mueller et al. 2005; Schultz & Brady 2008; Mueller & Rabeling 2008) and origins and maintenance of biodiversity (reviewed in LaSalle & Gauld 1993). Given their ubiquity, diversity, biological significance and importance to ecological and agricultural systems, resolving evolutionary relationships among Hymenoptera is critical – from the deepest splits (c. 220–300 Ma) within the Hymenoptera tree (Grimaldi & Engel 2005; Ronquist et al. 2012) to moderately deep divergences (c. 120–60 Ma) comprising key events in the evolution of both the ecologically dominant ants (the ‘Dynastic-Succession’ hypothesis of (Wilson & Hölldobler 2005)) and pollinating bees (Danforth et al. 2013) to the very shallow divergences among lineages that may be undergoing ecological (Savolainen & Vepsäläinen 2003) or symbiont-driven speciation (Mehdiabadi et al. 2012). Prior molecular phylogenetic studies have made significant advances towards resolving the relationships between higher-level taxonomic groups (Sharkey 2007; Pilgrim et al. 2008; Heraty et al. 2011; Debevec et al. 2012; Klopstein et al. 2013) and elucidating taxonomic relationships among species at shallower levels (reviewed in Moreau 2009; Danforth et al. 2013). However, these studies have been limited to analysing a relatively small number of nuclear or mitochondrial loci (e.g. Brady et al. 2006; Danforth et al. 2006; Sharanowski et al. 2010) that sample a small fraction of the genome.

Phylogenomic projects, such as the I1KITE initiative (http://www.1kite.org), seek to remedy this shortfall by identifying orthologous loci from widespread transcriptome sequencing. Although this approach has proven effective within Hymenoptera (Johnson et al. 2013), RNA-based techniques, on their own, limit the source materials usable for phylogenetic inference to fresh or properly preserved tissue (e.g. tissues stored in liquid nitrogen or RNAlater). This restriction leaves the majority of insect specimens unusable, especially those materials found in museum collections, posing a significant challenge for studies requiring rarely collected species. Thus, a significant challenge that remains for hymenopteran phylogenetics is to identify a large suite of universal markers that can be applied to samples stored with minimal preservation while maintaining the capability to elucidate relationships among lineages across a diversity of timescales.

Recent research among vertebrates has shown that target enrichment of highly conserved genomic sequences or ‘ultraconserved elements’ (UCEs; Faircloth et al. 2012) provides one mechanism for meeting this challenge. UCEs are an ideal marker for phylogenetic studies as a result of their ubiquity among taxonomic groups (Siepel et al. 2005), low paralogy (Derti et al. 2006) and low saturation (McCormack et al. 2012). While we still do not understand the evolutionary forces driving the conservation of UCEs (Harmston et al. 2013) or their biological function (Bejerano et al. 2004; Sandelin et al. 2004; Ahituv et al. 2007), target enrichment of UCE loci has been used to investigate several outstanding phylogenetic questions at ‘deep’ timescales across diverse groups of vertebrate taxa (Crawford et al. 2012; McCormack et al. 2013; Faircloth et al. 2013). The technique is also useful for understanding shallower, population-level events including recent divergences (Smith et al. 2014). When combined with massively parallel sequencing, the scalability of the UCE approach allows researchers to parallelize the collection of data from hundreds or thousands of orthologous loci across hundreds of taxa using stable DNA inputs in a single sequencing run; reduce the data analysis burden relative to what is required for the sequencing, assembly and alignment of multiple genomes; and conduct studies at a reasonable cost per individual.

Although enriching conserved loci resolves relationships among vertebrates, the utility of this approach among other animals is unknown. Here, we report the identification of a suite of c. 1500 UCE loci useful for inferring phylogenetic relationships across the entire Hymenoptera order. We used an in silico analysis to show that UCE loci recover the expected relationships among extant, genome-enabled, hymenopteran taxa with high support. We then synthesized a bait (i.e. probe) set for targeted enrichment of UCE loci, and we used the bait set to enrich an average of 721 loci among 30 sequence-tagged genomic libraries prepared from a diverse group of hymenopteran DNA sources, some of which were minimally preserved in ethanol for more than 12 years (Table S1, Supporting information). Using contigs assembled from massively parallel sequencing reads of these enriched libraries, we inferred the evolutionary relationships among hymenopteran taxa spanning very deep (≥220 Ma; estimated age of crown-group Hymenoptera; Grimaldi & Engel 2005; Ronquist et al. 2012) to very shallow (≤1 Ma; estimated age of included Nasonia species; Werren et al. 2010) divergences, and we discuss our findings relative to both phylogenomic and traditional efforts to resolve the hymenopteran phylogeny.
Materials and methods

Identification of UCEs

To identify a large set of UCE loci shared among Hymenoptera, we used LASTZ (Harris 2007) and programs from the UCE-PROBE-DESIGN package (UPDP) (https://github.com/faircloth-lab/uce-probe-design). We aligned repeat-masked (Smit et al. 1996-2010) genome assemblies of Apis mellifera (apiMel4; Honeybee Genome Sequencing Consortium 2006) and Nasonia vitripennis (nasVit2; Werren et al. 2010) using LASTZ. Following sequence alignment, we used rename_maf.py from UPDP to annotate the resulting multiple alignment format (MAF) lines with each taxon name. Following annotation, we used summary.py to search the resulting MAF file for aligned regions longer than 40 base pairs that were 100% conserved. We identified 2906 conserved regions meeting these criteria, and we filtered these regions for duplicate hits using an additional LASTZ alignment of conserved regions back to themselves (all-to-all) followed by removal of matches that were more than 80% identical over 50% of their length. After removing these duplicate-like regions, we output a file of 1555 nonduplicated UCE regions from the nasVit2 genome assembly. This buffering process allowed us to tile 120 nucleotide enrichment baits across the desired target regions at 2X tiling density (i.e. baits overlap by 60 bp; Tewhey et al. 2009) using py_tiler.py from the UPDP. This program also removed any resulting baits containing ambiguous base calls, having a large proportion (>25%) of repetitive sequence or having a high GC content (>70%). We screened the resulting bait sequences against themselves to remove duplicate baits from the set that sometimes resulted from slicing longer, unique UCE loci into smaller, 120 nucleotide chunks. We refer to this final set of baits as the ‘UCE bait set’ below.

In silico test of UCEs

We performed an in silico test of the ability of the UCE baits and their target UCE loci to resolve the phylogeny of Hymenoptera by aligning the UCE bait set to 14 hymenopteran genome assemblies downloaded from NCBI (Table S2, Supporting information) using a parallel wrapper around LASTZ (run_multiple_lastzs_sqlite.py) from the PHYLUCE (https://github.com/faircloth-lab/phyluce) package. Although genome assemblies exist for additional hymenopteran taxa, we were not granted permission to include these data in our analyses. Following alignment, we sliced the UCE loci from each genome and retained ±1000 bp of flanking sequence to the 5’ and 3’ end of each UCE using slice_sequence_from_genomes2.py. This program makes a first pass at removing duplicate hits during the slicing process. After slicing, and to identify assembled contigs representing UCE loci from each species using the standard PHYLUCE pipeline, we aligned species-specific UCE slices to a FASTA file of all enrichment baits using match_contigs_to_loci.py from the PHYLUCE package. This program implements the matching process using LASTZ and ensures that matches are 80% identical over 80% of their length. This program also screens and removes apparent duplicate contigs or contigs that are hit by baits targeting more than one UCE locus. After screening and removing nontarget and duplicated or misassembled contigs, the program creates a relational database containing two tables – one that holds the status of each UCE locus in each taxon (detected/nondetected) and another that maps the contig names generated by the assembler to the names of the corresponding UCE locus across all taxa.

We created a file containing the names of 14 genome-enabled taxa (Table S2, Supporting information), and we input this list to an additional program (get_match_counts.py) that queries the relational database described above to generate a list of UCE loci shared among taxa. We input the list of loci generated by this program to another program (get_fastas_from_match_counts.py) to create a monolithic FASTA file containing all UCE sequence data for all taxa. We separated the FASTA file of sliced sequences by locus and aligned all loci using a parallel wrapper (seqcap_align_2.py) around MAFFT (version 7.130; Katoh et al. 2005). Following MAFFT alignment, we removed the locus names from all alignments, edge-and internally trimmed resulting alignments using the TRIMAL ‘automated1’ algorithm (Capella-Gutierrez et al. 2009), converted trimmed alignments back to nexus format (convert_one_align_format_to_another.py), and selected the subset of alignments (get_only_loci_with_min_taxa.py) that were 70% complete (those that contained alignment data from at least 10 of 14 taxa). We generated alignment statistics and computed the number

© 2014 John Wiley & Sons Ltd
of informative sites across all alignments using get_align_summary_data.py and get_informative_sites.py. We concatenated the resulting alignments into a PHYLIP-formatted supermatrix (format_nexus_files_for_raxml.py), we conducted 20 maximum-likelihood (ML) searches for the phylogenetic tree that best fit the data using the unpartitioned supermatrix, RAxML (version 8.0.19; Stamatakis 2006) and the GTR+GAMMA model. Following the best tree search, we used RAxML to generate 100 nonparametric bootstrap replicates, we tested bootstrap replicates for convergence, and we reconciled the best fitting ML tree with the bootstrap replicates, all using features of RAxML.

Library preparation, target enrichment and sequencing of UCEs

Following the in silico test of the UCE bait set, we had probes commercially synthesized as an RNA target capture array (‘MYBaits’; MYcroarray, Inc.). We then extracted DNA from 30 hymenopteran species (Table S1, Supporting information) using either DNeasy extraction kits (Qiagen, Inc.) or phenol–chloroform (Maniatis et al. 1982) extraction procedures. We selected taxa for extraction and library preparation that span a range of divergence dates (≥220 to <5 Ma) and that represent major divisions within the order (sawflies, parasitoid wasps and stinging wasps). Following extraction we quantified DNA for each sample using a Qubit fluorometer (Life Technologies, Inc.), we randomly sheared 69–509 ng (400 ng mean) DNA to a target size of approximately 650 bp (range 400–800 bp) by sonication (Q800 or Diagenode BioRuptor; Qsonica Inc.), and we input the sheared DNA into a modified genomic DNA library preparation protocol (Kapa Biosystems) that incorporated ‘with-bead’ cleanup steps (Fisher et al. 2011) using a generic SPRI substitute (Rohland & Reich 2012; hereafter SPRI). This protocol is similar to the Kapa Biosystems protocol that uses commercial SPRI chemistry for cleanup and includes end-repair, adenylation and T/A ligation steps, except that the Fisher modification does not remove and replace SPRI beads between each step. Rather, the with-bead protocol removes and replaces a 25 μL NaCl + PEG solution, leaving the beads in-solution throughout the library preparation steps until their removal just prior to PCR amplification of the library. During adapter ligation, we also substituted custom-designed sequence-tagged adapters to the ligation reaction (Faircloth & Glenn 2012). Following adapter ligation, we PCR amplified 50% of the resulting library volume (c. 15 μL; 50–400 ng) using a reaction mix of 25 μL HiFi HotStart polymerase (Kapa Biosystems), 5 μL of Illumina TruSeq primer mix (5 μM each) and 5 μL double-distilled water (ddH2O) using the following thermal protocol: 98°C for 45 s; 10–12 cycles of 98°C for 15 s, 60°C for 30 s, 72°C for 60 s; and a final extension of 72°C for 5 min. We purified resulting reactions using 1X SPRI, and we rehydrated libraries in 33 μL ddH2O. We quantified 2 μL of each library using a Qubit fluorometer. We combined groups of six libraries at equimolar ratios into enrichment pools having a final concentration of 147 ng/μL.

We prepared Cot-1 DNA from nest collections of several ant species (Aphaenogaster fulva, Aphaenogaster ruidis and Formica subsericea) following the protocol of Timoshevskiy et al. (2012). We followed library enrichment procedures for the MYcroarray MYBaits kit (Blumenstiel et al. 2010), with three modifications: (i) we added 100 ng MYBaits to each reaction (a 1:5 dilution of the standard MYBaits concentration), (ii) we added 500 ng custom blocking oligos designed against our custom sequence tags and using 10 inosines to block the 10 nucleotide index sequence and (iii) for a subset of the pools (three pools, 18 samples), we tested the efficiency of our hymenopteran Cot-1 DNA by performing duplicate enrichments adding 500 ng of hymenoptera Cot-1 versus 500 ng commercially available chicken Cot-1 DNA (Applied Genetics Laboratories, Inc.). We excluded the remaining two pools from the test and used hymenoptera Cot-1 with each. We ran the hybridization reaction for 24 h at 65°C. Following hybridization, we bound all pools to streptavidin beads (MyOne C1; Life Technologies) and washed bound libraries according to a standard target enrichment protocol (Blumenstiel et al. 2010).

We used two different approaches for PCR recovery of the enriched libraries. For 12 of the samples (Table S1, Supporting information), we followed the standard (Blumenstiel et al. 2010) post-enrichment approach where we dissociated enriched DNA from RNA baits bound to streptavidin-coated beads with 0.1 N NaOH, followed by a 5-min neutralization of NaOH using an equal volume of 1 M Tris-HCl, a 1X SPRI cleanup and elution of the SPRI-purified sample in 30 μL of ddH2O. For the remaining 18 samples, we removed the final aliquot of wash buffer following enrichment and allowed samples to dry for five minutes while sitting in a magnet stand. We removed residual buffer with sterile toothpicks. Then, we added 30 μL ddH2O to each sample and proceeded directly to PCR recovery while the enriched libraries were still bound to streptavidin beads (Fisher et al. 2011). The streptavidin beads do not inhibit PCR and with-bead PCR recovery of enriched libraries is a faster and easier procedure. We combined either 15 μL of unbound, SPRI-purified, enriched library or 15 μL of streptavidin bead-bound, enriched library in water with 25 μL HiFi HotStart Taq (Kapa Biosystems), 5 μL of Illumina TruSeq primer mix (5 μM each) and 5 μL of ddH2O.
We ran PCR recovery of each library using the following thermal profile: 98°C for 45 s; 16–18 cycles of 98°C for 15 s, 60°C for 30 s, 72°C for 60 s; and a final extension of 72°C for 5 m. We purified resulting reaction using 1.8X SPRI, and we rehydrated enriched pools in 33 μL ddH2O. We quantified 2 μL of each enriched pool using a Qubit fluorometer.

Following quantification of the enriched pools, we verified enrichment and compared the utility of chicken Cot-1 to hymenopteran Cot-1 by designing primers (Untergasser et al. 2012) to amplify seven UCE loci (Table S3, Supporting information) targeted by the baits we designed. We set up a relative qPCR by amplifying two replicates of 1 ng of enriched DNA from each library at all seven loci and comparing those results to two replicates of 1 ng unenriched DNA for each library at all seven loci. We performed qPCR using a SYBR Green qPCR kit (Hoffman-LaRoche, Ltd.) on a Roche LightCycler 480. Following data collection, we computed the average of the replicate crossing point (Cp) values for each library at each amplicon for each Cot-1 treatment, and we computed fold-enrichment values, assuming an efficiency of 1.78 and using the formula 1.78Cp (enriched Cp – unenriched Cp).

Following qPCR verification and selection of the library pools that showed the greatest fold enrichment for a given Cot-1 treatment (chicken or hymenopteran), we diluted each pool to 2.5 ng/μL for qPCR library quantification. Using the diluted DNA, we qPCR quantified libraries using a library quantification kit (Kapa Biosystems) and assuming an average library fragment length of 500 bp. Based on the size-adjusted concentrations estimated by qPCR, we created two different equimolar pools of libraries at 10 pmol concentration (Table S1, Supporting information), and we sequenced 9–10 pmol of each pool-of-pooled libraries using two runs of paired-end, 250 bp sequencing on an Illumina MiSeq (v2; UCLA Genotyping Core Facility).

**Analysis of captured UCE data**

We trimmed and demultiplexed FASTQ data output by BaseSpace for adapter contamination and low-quality bases using a parallel wrapper (https://github.com/faircloth-lab/illumiprocessor) around Trimmmomatic (Bolger et al. 2014). Following read trimming, we computed summary statistics on the data using get_fastq_stats.py from the PHYLUCE package. To assemble the cleaned reads, we generated separate data sets using wrappers around the programs Trinity (version trinityrnaseq-r2013-02-25; assemblo_trinity.py; Marcais & Kingsford 2011; Grabherr et al. 2011) and ABYSS (version 1.3.6; assemblo_abyss.py; Simpson et al. 2009). For both assemblies we computed coverage across assembled contigs using a program (get_trinity_coverage.py) that realigns the trimmed sequence reads to each set of assembled contigs using BWA-MEM (Li 2013), cleans the resulting BAM files using PICARD (version 1.99; http://picard.sourceforge.net/), adds read-group (RG) information to each library using PICARD, indexes the resulting BAM file using SAMTOOLS (Li et al. 2009) and calculates coverage at each base of each assembled contig using GATK (version 2.7.2; Van der Auwera et al. 2009; McKenna et al. 2010; DePristo et al. 2011).

To identify assembled contigs representing enriched UCE loci from each species, we aligned species-specific contig assemblies from both sequence assembly programs to a FASTA file of all enrichment baits using match_contigs_to_loci.py, as described above. We created a file containing the names of 30 enriched taxa from which we collected data (Table S1, Supporting information), as well as the names of 14 genome-enabled, hymenopteran taxa (Table S2, Supporting information), and we input this list to an additional program (get_match_counts.py) that queries the relational database created by matching baits to assembled contigs, as well as the relational database containing UCE match data for genome-enabled taxa (created as part of the in silico tests), to generate a list of UCE loci shared among all taxa. We input the list of loci generated by this program to an additional program (get_fastas_from_match_counts.py) to create a monolithic FASTA file containing all UCE sequence data for all taxa. We aligned all data in the monolithic FASTA file using MAFFT (Katoh et al. 2005) and seqcap_align_2.py, as described above. Following MAFFT alignment, we removed the locus names from all alignments (remove_locus_name_from_nexus_lines.py), edge- and internally trimmed resulting alignments using the ‘automated1’ algorithm implemented in TRIMAL (Capella-Gutierrez et al. 2009), converted trimmed alignments back to nexus format (convert_one_align_format_to_another.py) and selected the subset of alignments (get_only_loci_with_min_taxa.py) that were 75% complete (those that contained alignment data from at least 33 of 44 individuals). We generated alignment statistics and computed the number of informative sites across all alignments using get_align_summary_data.py and get_informative_sites.py.

We concatenated the resulting alignments into a PHYLIP-formatted supermatrix (format_nexus_files_for_raxml.py) and conducted 20 maximum-likelihood (ML) searches for the phylogenetic tree that best fit the data using the unpartitioned supermatrix, RAxML (Stamatakis 2006), and the GTRGAMMA model. Following the best tree search, we used RAxML to generate 100 nonparametric bootstrap replicates, we tested bootstrap replicates for convergence, and we reconciled the best fitting ML tree with the bootstrap replicates.
Results

Identification of UCEs

We identified 1510 nonduplicate, 60 bp regions of 100% conservation across the alignments of \textit{apiMel4} to \textit{nasVit2}, and we designed a capture bait set containing 2749 probes targeting these 1510 loci.

\textit{In silico} test of UCEs

During our \textit{in silico} tests, we located an average of 863.7 (95 CI: 98.3) unique UCE loci across genome-enabled hymenopteran species (Table S2, Supporting information). Following identification and filtering for uniqueness, sequence slicing, sequence alignment and trimming of resulting alignments, we generated a 70% complete matrix containing 721 UCE loci and having a mean alignment length of 1434 base pairs (95 CI: 35.5). These loci contained an average of 819 informative sites per locus, and concatenation of all loci in the complete matrix produced a supermatrix of 1 033 906 bp containing 591 033 informative sites. The phylogeny inferred from these results (Fig. S1, Supporting information) reconstructs the established relationships among genome-enabled hymenopteran lineages (Brady et al. 2006; Werren et al. 2010; Heraty et al. 2011; Oxley et al. 2014) with complete support.

\textit{In vitro} test of UCEs

We extracted an average of 1894 ng DNA (181–6480 ng) from each hymenopteran species and input an average of 400 ng (69–509 ng) to the library preparation process. Following library prep, PCR amplification and SPRI purification, DNA libraries contained approximately 100 ng DNA (53–151 ng). Fold-enrichment values of enriched libraries estimated by qPCR suggested that commercial chicken Cot-1 performed better than the hymenopteran Cot-1 we prepared by approximately 249, 342) reads per sample. Reads averaged 192.6 bp (95 CI: 3.7) following demultiplexing, quality- and adapter-trimming (Table S5, Supporting information). Using Trinity (Table 1), we assembled these DNA reads into an average of 74 140 contigs of 347.7 bp in length (95 CI: 6.9) and having a mean coverage of 4.1X (95 CI: 0.3). Using ABvSS (Table S6, Supporting information), we assembled these DNA reads into an average of 143 863 contigs of 202.7 bp in length (95 CI: 5.1) and having a mean coverage of 3.8X (95 CI: 0.2).

After searching for UCEs within the Trinity assemblies (Table 1; Table S7, Supporting information), we enriched an average of 721 (95 CI: 48.2) unique UCE loci, the average locus length was 1010 bp (95 CI: 66.1), the average coverage per enriched UCE locus was 52.3X (95 CI: 9.4), and the mean percentage of reads-on-target was 30% (95 CI: 2.7%). When searching against the ABvSS assemblies (Tables S6 and S8, Supporting information), we enriched an average of 477 (95 CI: 56.4) unique UCE loci, the average locus length was 669.1 bp (95 CI: 36.9), the average coverage per enriched UCE locus was 40.7X (95 CI: 5.1), and the mean percentage of reads-on-target was 12.5% (95 CI: 3%). These and other summary statistics on assemblies (Fig. S2, Supporting information) suggest that Trinity-assembled UCE contigs have more desirable properties for downstream phylogenetic analyses, in aggregate, than ABvSS assemblies.

Following alignment of the Trinity-assembled data, alignment trimming and filtering of loci having fewer than 33 taxa (75% complete), we retained 600 alignments having an average length of 691.4 bp (95 CI: 44.4 bp). The average number of taxa present in these 600 alignments was 39.2 (95 CI: 0.2). The concatenated, Trinity supermatrix contained 414 849 bp, 413 782 total nucleotide characters and 282 973 informative sites. Following alignment of the ABvSS-assembled data, alignment trimming and filtering of loci having fewer than 33 taxa (75% complete), we retained 196 alignments of 522.5 bp (95 CI: 82.1 bp) in length. The average number of taxa present in these 196 alignments was 36.71 (95 CI: 0.37). The concatenated, ABvSS supermatrix contained 102 418 bp, 102 148 total nucleotide characters and 60 714 informative sites.

We inferred a phylogeny from both Trinity assemblies (Fig. 1) and ABvSS assemblies (Fig. S3, Supporting information). Because the Trinity assemblies produced a larger number of longer, higher coverage UCE loci that yielded a larger, 70% complete, concatenated supermatrix, we focus on the relationships we inferred from the Trinity data. However, the ABvSS topology (Fig. S3, Supporting information), while having slightly lower support at several nodes, was identical to the topology we inferred from the Trinity assemblies.

Generally, the relationships among Hymenoptera we inferred from the Trinity supermatrix (Fig. 1) accurately reconstructed: (i) the relationships among genome-enabled hymenopterans inferred during our \textit{in silico} analysis, (ii) the established relationships between taxa...
from which we collected data, de novo and (iii) the established relationships between genome-enabled taxa and species from which we collected data (Danforth et al. 2006; Brady et al. 2006; Werren et al. 2010; Heraty et al. 2011; Branstetter 2012; Oxley et al. 2014; Ward et al. 2014).

In Fig. 1, the sawflies, represented here by only the superfamil y Tenthredinoidea, formed a clade sister to the Apocrita. Within the Apocrita, parasitic wasps formed a polyphyletic grade leading to a monophyletic Aculeata (stinging wasps, ants and bees) with Orthog onalys (Trigonidae)+Evaniella (Evaniiidae) recovered as sister to the aculeates. Within Aculeata, we recovered five main groups with maximum support (note that we did not include chrysidoid wasps): ants (Formicidae), sphaeciform bees+wasps (Apoidea), vespid wasps (Ves- pidiae), scolid wasps (Scoliidae) and tiphioid-pompiloid wasps (Chyphotidae+Pompilidae+Sapygidae). Among these groups, we inferred the ants to be sister to a clade containing all remaining aculeate lineages with maximum support. Within the clade containing the remaining aculeates, we recovered the Scoliidae as sister to the Apoidea (87% support), and we recovered the Vespidae as sister to the tiphioid-pompiloid wasps (58% support). Within the ants, we recovered all expected relationships among the five included subfamilies (Ponerinae, Dorylinae, Dolichoderinae, Formicinae and Myrmicinidae; Brady et al. 2006; Moreau & Bell 2013), and several closely related ant genera and species belonging to the tribe Stenammini (Aphaenogaster, Messor and Stenamma; Branstetter 2012; Ward et al. 2014) with high (≥87%) support.

</table>
To test the effects of removing distantly related sawfly lineages on the topology and support inferred across the UCE data, we constructed a new UCE data set lacking sawfly lineages because the sawfly data were the most incomplete, with respect to counts of recovered loci across all taxa (see Fig. S4, Supporting information and below), and the inclusion of sawflies had the largest effect on the size of our incomplete matrix. This new data set (75% complete) included 638 UCE loci, contained an average of 37.2 taxa (95 CI: 0.2), and had an average alignment length of 737.1 bp (95 CI: 46.4). The supermatrix contained 470 258 bp, 469 081 total nucleotide characters and 310 253 (+27 280) informative sites. Following inference from this updated data set with RAxML using

---

Fig. 1 Maximum-likelihood phylogeny inferred from a 75% complete supermatrix containing data from 14 genome-enabled taxa (identified by double-asterisks) and 30 taxa from which we enriched and assembled (Trinity) ultraconserved element loci. We show bootstrap support values only where support is <100%, and the single asterisk beside Stenamma megamanni denotes that this sample represents a different population of the same species.
approaches identical to those described above, the resulting phylogeny (Fig. S6, Supporting information) had the same topology as the tree including sawflies with the exception of inferred relationships between two nonaculeate taxa, *Evaniella* and *Orthognalys*.

**Analysis of capture success**

Based on the differences in capture success we observed across the resulting phylogeny (Fig. S4, Supporting information), we analysed several summary metrics (Tables S7 and S8, Supporting information), post hoc, using general linear models (R, version 2.5.12; Team 2011) to investigate those parameters affecting the number (Poisson link function) and length (Gaussian link function) of UCE loci we recovered. With these values, we also included an explicit measure of pairwise genetic distance between all taxa from which we enriched sequence data and the *nas Vit*2 genomic assembly, from which we designed capture baits. We estimated distance values from the concatenated Trinity supermatrix using the ‘distance’ method of PhyCogent (version 1.5.3; Knight et al. 2007) assuming a GTR site rate substitution model. We used Akaike’s information criteria (AIC) to rank and compare linear models, and we model-averaged estimates across parameters where there was a valid set ($\omega_I > 0.10$; Royall 1997) of candidate models. These post hoc analyses suggest that UCE capture success may be driven by several factors, in addition to phylogenetic distance between the probe design source and the taxa being enriched. Specifically, Akaike weights suggest that a ‘global’ model containing four parameters (distance + reads + mean read length + assembly method) best approximates the data (Table S9, Supporting information), that there are large differences among parameter effect sizes (Fig. S5, Supporting information), and that phylogenetic distance has the largest effect of parameters we investigated on the number of UCE contigs enriched.

The size of this effect is tempered somewhat when considering only the Trinity assemblies, where read length appears to play a role (Table S10, Fig. S5, Supporting information). Similarly, length of enriched UCE contigs may best be explained (Table S11, Supporting information) by a global model containing three parameters (distance + reads + assembly method), assembly method probably plays a larger role in resulting length of UCE loci, and phylogenetic distance retains a large effect on resulting contig length (Fig. S5, Supporting information). When considering only the Trinity assemblies, the effects of distance and the number of reads are both important factors affecting resulting contig length (Fig. S12, Supporting information). In all of these results, it is important to keep in mind that phylogenetic distance falls on the interval [0,1], so the effect size of this parameter is tempered by typically small changes in its value.

**Discussion**

We have developed a powerful new genomic tool for estimating phylogenetic relationships among members of the hyperdiverse insect order Hymenoptera. By extending and improving prior work (Faircloth et al. 2012), we identified over 1500 highly conserved genomic regions between distantly related Hymenoptera taxa, collected these loci from 14 genome-enabled and 30 non-genome-enabled taxa using in silico and in vitro techniques and used the resulting genome-scale sequence data to accurately infer both deep (c. 220–300 Ma) and relatively shallow (≤1 Ma) relationships. Although other phylogenomic approaches have been employed among arthropods (Johnson et al. 2013), this is the first time that sequence capture of conserved regions has been used to collect genome-scale DNA data from this group.

Compared to recent phylogenetic studies investigating higher-level relationships within Hymenoptera (Sharkey 2007; Heraty et al. 2011; Klopstein et al. 2013), the UCE data recovered all well-established relationships with complete support. In addition, the UCE data suggest a novel relationship within the Aculeata, in which the ants are sister to all remaining aculeate lineages included here. The aculeates contain all major lineages of social insects (except termites) including ants, vespid wasps and several lineages of social bees. Aculeata also includes the most important group of pollinators (bees). Hence, understanding relationships among the aculeates is critical to provide the comparative framework needed to study the origins and evolution of sociality and pollination biology in this group (Danforth 2013). Until recently, phylogenetic studies of aculeates have been based on a relatively small number of characters and have produced conflicting results (Brothers 1999; Pilgrim et al. 2008; Peters et al. 2011; Debevec et al. 2012). A recent transcriptome-based study (Johnson et al. 2013) sequenced key lineages within Aculeata and produced a fully resolved phylogeny of aculeate lineages, recovering a novel relationship in which ants are sister to the Apoidea (spheciform bees+wasps). Our UCE data set did not recover this relationship. Instead, we found ants to be sister to all remaining aculeate lineages with complete support, but there were several nodes within each clade receiving moderate (≥58%) support. Our study also differed from Johnson et al. (2013) in the placement of vespid wasps as sister to the tiphioid-pompiloid wasps (Chyphotidae+Pompilidae+Sapygidae) and the scoliid wasps as sister to the spheciform wasps+bees (Apoidea). Previous work by Debevec et al. (2012) also recovered...
this placement of scoliid wasps as sister to the spheciform wasps−bees.

Given the importance of resolving relationships among aculeate lineages, we tested the effects of removing sawfly lineages on the topology and support inferred across the UCE tree presented in Fig. 1. Following inference from this updated data set with RAxML, the resulting phylogeny (Fig. S6, Supporting information) had the same topology as the tree including sawflies, except that in Fig. 1, two nonaculeate taxa, E venti lla and Orthogonalys form a clade with maximum support, while in Fig. S6 (Supporting information), these taxa form a grade, also with maximum support. Support values for internal nodes were marginally higher in the tree excluding sawflies. The stability of the recovered relationships within Aculeata between these two trees and across different assembly methods suggests that neither the count of loci, nor the total amount of data, nor the assembly approach are driving the differences we observed between our results and those of Johnson et al. (2013).

Rather, taxon sampling (e.g. our study does not include any chrysidoid wasps) or other differences among each data set including size, analytical approach, nucleotide composition, locus type, the number of independent loci sampled and matrix completeness could explain the differences in topology we observed. For example, Johnson et al. (2013) collected and analysed both larger and smaller amounts of data (175 404–3 001 657 sites) of a different type (amino acid residues) from fewer taxa (n = 19) that included variable counts of loci (308–5214 genes) spanning a range of matrix completeness (50–100%), and they inferred their phylogeny using concatenated maximum likelihood, concatenated Bayesian and summary-statistic gene tree species tree approaches. In contrast, we collected and analysed a less variable amount of data (102 418–469 081 sites), from a larger number of taxa (n = 41–43) that included variable counts of loci (196–638 loci) spanning a small range of matrix completeness (70–75%). We inferred the phylogeny using a concatenated maximum-likelihood approach. The types of differences between these two studies and their effects on phylogenetic reconstruction are the sorts of questions that deserve the bulk of current and future analytical effort in phylogenomics.

Focusing within ants, we captured an average of 748 UCE loci (95 CI: 5.0) using the bait set we designed and inferred nearly all relationships with complete support. The relationships we recovered among ant subfamilies agree with several recent molecular phylogenies of ants (Moreau et al. 2006; Brady et al. 2006; Moreau & Bell 2013). Furthermore, most relationships within the tribe Stenammini (Aphaenogaster, Messor and Stenamma), including relationships within Stenamma, agree with recent molecular studies (Moreau et al. 2006; Brady et al. 2006; Branstetter 2012; Moreau & Bell 2013). Our study also agrees with a recent 11-gene phylogeny that documents the nonmonophyly of the genus Aphaenogaster (Ward et al. 2014). These observations are important because they demonstrate the potential for using UCEs to resolve shallow relationships within the Hymenoptera (divergence dates among Stenamma species are estimated at c. 35 to <5 Ma; Branstetter 2012) similar to results from UCE data collected among vertebrates (Faircloth et al. 2013; Smith et al. 2014).

A major advantage of the UCE approach we describe over transcriptome-based methods is that it does not require specially preserved tissues. Here, we successfully extracted and enriched DNA from insect specimens that ranged from 12 years old to weeks old using a variety of collection methods, including several that were suboptimal for DNA preservation (ethanol preserved or dry pinned) and resulted in the extraction of little DNA (Table S1, Supporting information). Furthermore, we successfully generated and enriched UCE loci from genomic libraries constructed using as little as 70 ng of DNA. This finding is significant because many arthropod taxa are small, yielding very low amounts of DNA, and our results suggest we can successfully prepare and enrich libraries from low DNA inputs. New library preparation approaches, including the Hyper Prep Kit (Kapa Biosystems) and the NEBNext Ultra Kit (New England Biolabs), should make it possible to use even less DNA in the future without resorting to expensive modifications of protocol. The ability to use small, moderately old and sometimes low-quality specimens with the UCE approach we describe means that much of the available materials in museums and other collections can be used as a DNA source for phylogenomic studies – making it possible to sequence very rare and, often, very important taxa.

**Acknowledgements**

We thank Alex Buerkle, Jennifer Mandel and three anonymous reviewers for their comments, which improved this manuscript. We thank Dave Smith, Ana Jesovnik, Jack Longino, Phil Ward, Brian Fisher, Peter Hawkes, Jim Carpenter, James Pitts, Gary Hevel and Sam Droege for providing some of the tissue samples we used. Hong Zhao helped with DNA extraction, and Alex Chase assisted with library preparation. We thank Uma Dande kar and Hemani Wijesuriya for performing MiSeq runs and Travis Glenn for helpful discussions. Phil Ward provided insightful comments regarding our results and relationships within the Aculeata. To make the cartoon Hymenoptera used in Fig. 1, we altered open-access or public domain photographs taken by the following individuals: Bob Peterson (Camponotus sp.), Srikanta h Sekar (Harpeggnathos sp.), Gilles San Martin (Stenamma sp.), Christophe Quintin (Taxonus sp.), Franco Folini (Apis sp.), M.E. Clark (Nasonia sp.), Muhammad Mahdi Karim (Cremasti nae), OpenCage (Vespidae) and DeadStar (Acromyrnex sp.). All
modified images are available as PSD files from figshare (doi:10.6084/m9.figshare.1173286).

Funding
A Smithsonian Institution grant from the Consortium for Understanding and Sustaining a Biodiverse Planet (to SGB, BCF, and NDW) provided most of the funding for this project and support for NDW’s participation. A Smithsonian Institution Buck Postdoctoral Fellowship and NSF grants DEB-1354739 and DEB-1354996 (project ADMAC) supported MGB. NSF DEB-1242260 (to BCF) and an Amazon Web Services Education Grant (to BCF) supported computational portions of this work. NSF EF-0431330 (to SGB) provided resources to obtain some specimens used in this study. This study was also supported in part by resources and technical expertise from the Georgia Advanced Computing Resource Center, a partnership between the University of Georgia’s Office of the Vice President for Research and Office of the Vice President for Information Technology.
